ARTICLE INFO

ABSTRACT

Continental intraplate basalts are widespread across Central-East Asia, and their melting mechanisms are poorly known. Herein, we present integrated studies of petrology, elemental-isotope systematics, and thermodynamic modeling of Cenozoic Liangcheng basalts, a representative volcanic field of the vast intracontinental basaltic magmatic province covering Central-East Asia, with the aim of constraining the source characteristics and melting dynamics in this intraplate setting. These basalts have moderate-to-low silica (45.2 to 49.0 wt%), high Fe_2O_3T (10.0 to 12.2 wt%), and alkali ($Na_2O + K_2O$, 4.27 to 7.38 wt%) contents with ocean-island basalt (OIB) -like trace-element patterns and moderately depleted to slightly enriched Sr–Nd–Pb–Hf isotopes ($^{87}Sr/^{86}Sr$ = 0.703924–0.705176, $^{143}Nd/^{144}Nd$ = 0.512540–0.512861, $^{206}Pb/^{204}Pb$ = 17.2752–17.9180, $^{207}Pb/^{204}Pb$ = 15.4860–15.7383, $^{208}Pb/^{204}Pb$ = 37.6995–38.3599, and $^{176}Hf/^{177}Hf$ = 0.282852–0.282999). The major elements (e.g., high Fe/Mn, low CaO) and olivine chemistry (e.g., high Ni, Zn/Fe, and low Mn/Zn) favor derivation from a silica-deficient pyroxenite-bearing source, while the trace-element and isotope systematics suggest the involvement of recycled components including oceanic slab and sediment (both terrigenous and pelagic). A grid search with a thermodynamic melting model using incompatible trace elements was carried out to impose quantitative constraints on the mantle source. The modeling results show that the source of the Liangcheng basalt contains 80% primitive mantle peridotite and 20% silica-deficient pyroxenite. This exercise and geobarometric calculation using major elements suggest that melting occurs at a potential temperature of 1380 °C underneath a thinned continental lithosphere with a basal pressure of ~2GPa, consistent with the source characteristics and melting conditions estimated for many other volcanic fields in the vast Central-East Asia magmatic province. By combining these results with the regional geology and tectonic history, we can suggest that these basalts were formed by decompression melting owing to mantle convection driven by lithospheric thickness variations (edge-driven convection). We suggest that such a melting scenario is ubiquitous beneath Central-East Asia and may have played a vital role in the formation of widespread intraplate continental alkaline basalts.

1. Introduction

Intraplate volcanism distributed far from plate boundaries is important for understanding the geodynamic processes of Earth's mantle (King and Ritsema, 2000; Sobolev et al., 2005; Hoernle et al., 2006; Conrad et al., 2011; Ballmer et al., 2013; Wang et al., 2015). While high-volume ($>10^5$ km^3) magmatism is usually fed by mantle plumes (Bryan and Ernst, 2008), some small-volume diffusive magmatism shows no obvious connection with plate-boundary processes or mantle

plumes (McGee and Smith, 2016). The origin of this intraplate volcanism remains unclear. The proposed models include: 1) splash plume triggered by cold downwelling material (Davies and Bunge, 2006); 2) passive upwelling caused by lithospheric thinning or rifting (Hoernle et al., 2006); 3) shear-driven upwelling related to relative motion between the lithosphere and asthenosphere (Conrad et al., 2011); 4) plate subduction-induced mantle upwelling (Kuritani et al., 2011); 5) edge-driven convection due to steps in lithospheric structure/thickness combined with plate movement (King and Ritsema, 2000).

The Central-East Asia continent became a coherent landmass after a series of Phanerozoic subduction and/or collision episodes, and it has witnessed widespread basaltic magmatism during the Cenozoic (Fig. 1A). P-wave tomography has revealed a stagnant subducted (Paleo-) Pacific plate in the mantle transition zone (Huang and Zhao, 2006), and the mantle domain above the plate is called the Big Mantle Wedge (BMW) (Zhao et al., 2004). Cenozoic basalts within the structure of the BMW span a wide composition range from extremely silica-deficient nephelinite to silica-excess quartz tholeiite (Xu et al., 2018). Lithological heterogeneous mantle sources containing garnet pyroxenite, eclogite, carbonated eclogite, and carbonated peridotite have been introduced to explain compositional variations (Liu et al., 2008a; Zeng et al., 2010, 2011, 2021; Huang et al., 2015; Li et al., 2017; Wang et al., 2017; He et al., 2019a; Yu et al., 2019; Xu et al., 2022; Zou et al., 2022). The melting of such lithological heterogeneities is generally interpreted to be related to the stagnant (Paleo-) Pacific slab in the mantle transition zone because of the spatial-temporal coincidence between the subducted slab and basalts (Figs. 1A, B; Chen et al., 2017; Xu et al., 2018; Cai et al., 2022), with some exceptions in which the melting is driven by small-scale convection due to lithospheric thickness variations (Guo et al., 2020; Sun et al., 2020; Xu et al., 2022). Cenozoic basalts beyond the BMW display geochemical compositions similar to their counterparts, and lithological heterogeneities have also been inferred from the source (He et al., 2019b; Pang et al., 2019; Sheldrick et al., 2020a; Zhang et al., 2021; Liu et al., 2022). However, unlike those within the BMW, basalts beyond the BMW are spatiotemporally far from any active margins (converge or disperse) (Windley et al., 2010; Xiao et al., 2015) and their melting mechanism remains hotly debated. Existing explanations include: 1) localized asthenospheric upwelling owing to lithospheric rifting or delamination (Barry et al., 2003; Hunt et al., 2012); 2) large-scale convection related to mantle plume (Johnson et al., 2005); 3) direct mantle melting triggered by coeval subduction/convergent processes, that is, subduction of the Pacific plate and/or India-Eurasia collision (Li et al., 2018; Chen and Faccenda, 2019). The above debates are largely owing to the lack of constraints on the thermal-chemical conditions of the lithologically heterogeneous mantle source, which are crucial for understanding the origin and melting mechanism of these intracontinental basalts.

Herein, we chose to study the Liangcheng basalts, which are far from the front edge of the stagnant Pacific slab (> 500 km) (Fig. 1B), to explore the mantle source characteristics and melting mechanisms of continental intraplate basalts. We present an integrated study on mineral chemistry, whole-rock geochemistry, Sr–Nd–Pb–Hf isotope compositions, and thermodynamic modeling to constrain their source characteristics and melting conditions. Our study reveals that these basalts originate from a silica-deficient pyroxenite-bearing mantle source with a low final melting pressure (~2 GPa) that corresponds to a thin lithosphere (< 70 km), which is consistent with most alkaline basalts in the studied and nearby regions. Our results, together with published geochemical data, geophysical observations, and regional geological history, suggest that decompression melting due to mantle convection driven by lithospheric thickness variations (edge-driven convection) may have played an important role in the formation of the Liangcheng basalts as well as many other Cenozoic intracontinental alkaline basalts across Central-East Asia.

2. Geological background and sample description

The Central-East Asia continent is composed of three cratons, including the Siberian Craton in the north, the North China Craton (NCC) in the middle, and the South China Craton in the south (Fig. 1A). Their assembly is marked by three major tectonic events, including the closure of the Paleo-Tethys Ocean between the South China Craton and the NCC before 200 Ma (Wu et al., 2009), the closure of the Paleo-Asian Ocean along the Solonker suture zone at 260–230 Ma (Wan et al., 2018; Jing et al., 2022), and the closure of the Mongol-Okhotsk Ocean along

the Mongol-Okhotsk suture zone at 155–120 Ma (Kravchinsky et al., 2002; Van der Voo et al., 2015). After these tectonic events, the three cratons were bounded by two complex orogenic belts, namely the Central Asia Orogenic Belt between the NCC and the Siberia Craton and the Qinling-Dabie-Sulu Ultra-High Pressure Orogenic Belt between the NCC and the South China Craton (Fig. 1A).

The subduction of the (Paleo-) Pacific slab that started at ~180 Ma has led to the development of N-NE trending faulting and rifting systems, vast magmatism, and large-scale graben basins, as well as the formation of the North-South gravity lineament (NSGL) in East Asia (Ma and Xu, 2021 and references therein). Cenozoic basaltic magmatism in East Asia mainly occurred along the N-NE trending deep major faults (e. g., the Tan-Lu fault in the eastern NCC and Yilan-Yitong and Fushun-Mishan faults in NE China, Fig. 1A) or around the graben basins (e.g., Songliao Basin, Fig. 1A). In contrast, Central Asia (areas west of the NSGL) remains an intracontinental setting since the closure of the Mongol-Okhotsk Ocean during the Late Mesozoic to Early Cretaceous (Van der Voo et al., 2015; Sheldrick et al., 2020b) and is now away from the western leading edge of the Pacific slab, as revealed by the P-wave images (Huang and Zhao, 2006). The lithospheric thickness of Central Asia shows significant variations, as illustrated by geophysical observations and Mesozoic-Cenozoic basalt-born mantle xenoliths (Ionov, 2002; Chen et al., 2009a; Dai et al., 2020). The ancient blocks (Ordos, Gobi, and Siberia) are generally thick (> 200 km), whereas the segments between these ancient blocks commonly have a thin lithosphere, and Cenozoic basaltic magmatism is preferentially spread in regions with thin lithosphere (Fig. 1A).

The Liangcheng volcanic field belongs to the western part of NCC and locates at the joint of the Yinchuan-Hetao basin and the Shaanxi-Shanxi rift system (Fig. 1A) and has a wide distribution area of 1500 km^2 (Li and Li, 2003). It is underlain by thin (<100 km) and fertile lithospheric mantle, as evidenced by garnet-free lherzolite xenoliths in Cenozoic basalts (Zhang et al., 2012; Zhao et al., 2021) and seismic tomography (Chen et al., 2009a; Huang et al., 2009). Lithospheric thinning was proposed to have occurred at some point during the Early Cretaceous and Cenozoic, based on the compositional variation of regional basalts (Guo et al., 2014). The Neogene basalts are interbedded with several layers of sedimentary rocks (coal, mudstone, sandstone, and volcanic breccia), and unconformably underlain by the Archean TTGs and Jurassic-Cretaceous sandstone, shale, and tuff breccia, and overlain by Quaternary loess and sandstone (Fig. 2). These basalts occur either as volcanic cones or as lava flows with typical columnar jointing (Fig. S1) and the thickness of volcanic strata is basically >200 m and can up to 300 m in the southeast of the volcanic field. Whole-rock K–Ar dating of this volcanic field yields ages ranging from Oligocene to Miocene (24–15 Ma; Li and Li, 2003).

Thirty samples from 13 volcanic cones and three lava flow fields were collected, and only fresh samples without mineral cumulates were selected to be analyzed to obtain geochemical data. These rocks show a dark-grey colour with a massive structure and aphyric or porphyritic texture. The phenocrysts are dominated by olivine, with minor clinopyroxene. Olivine phenocrysts are euhedral to subhedral with embayed absorption shapes and vary in size from 0.5 mm to 2 mm, with a total amount of 5 vol%. Cracks developed, but no deformation structures were observed in the olivine grains (Fig. S1). Clinopyroxenes are anhedral and irregular in shape with a size of 0.5–1 mm and 1 vol% in volume (Fig. S1). The groundmass consists of olivine, clinopyroxene, plagioclase, Fe–Ti oxide microcrystals, and glass. No obvious petrographic evidence of magma mixing or mingling (e.g., complex zoning) was observed in these samples.

3. Analytical methods

3.1. In-situ mineral chemistry analyses

In-situ mineral (olivine, clinopyroxene, and feldspar) major-element

Fig. 1. (A) Topography map of Central-East Asia and distribution of late Cenozoic intraplate volcanic province; the distribution patterns of major faults, basins, and magmatism are according to Wang et al. (2015), He et al. (2019b) and Yu et al. (2019). (B) Seismic tomography image of the deeply subducted Pacific slab and structure of big mantle wedge (after Huang and Zhao, 2006). F1, Xinlin-Xiguitu fault; F2, Hegenshan-Heihe fault; F3, Solonker-Xar Moron-Changchun-Yanji suture; F4, Chifeng-Kaiyuan fault; F5, Yitong-Yilan fault; F6, Jiamusi fault; F7, Dunhua-Mishan fault; F8, Tan-Lu fault; F9, Jiang-Shao fault; F10, Songxi-Changting, Zhenghe-Dapu, and Changle-Nan'ao faults. B1, Songliao basin; B2, Hailarr basin; B3, Tamsag basin; B4, Erlian basin; B5, East Gobi basin; B6, Yin'gen basin; B7, Yinchuan-Hetao basin; B8, Shaanxi-Shanxi rift system.
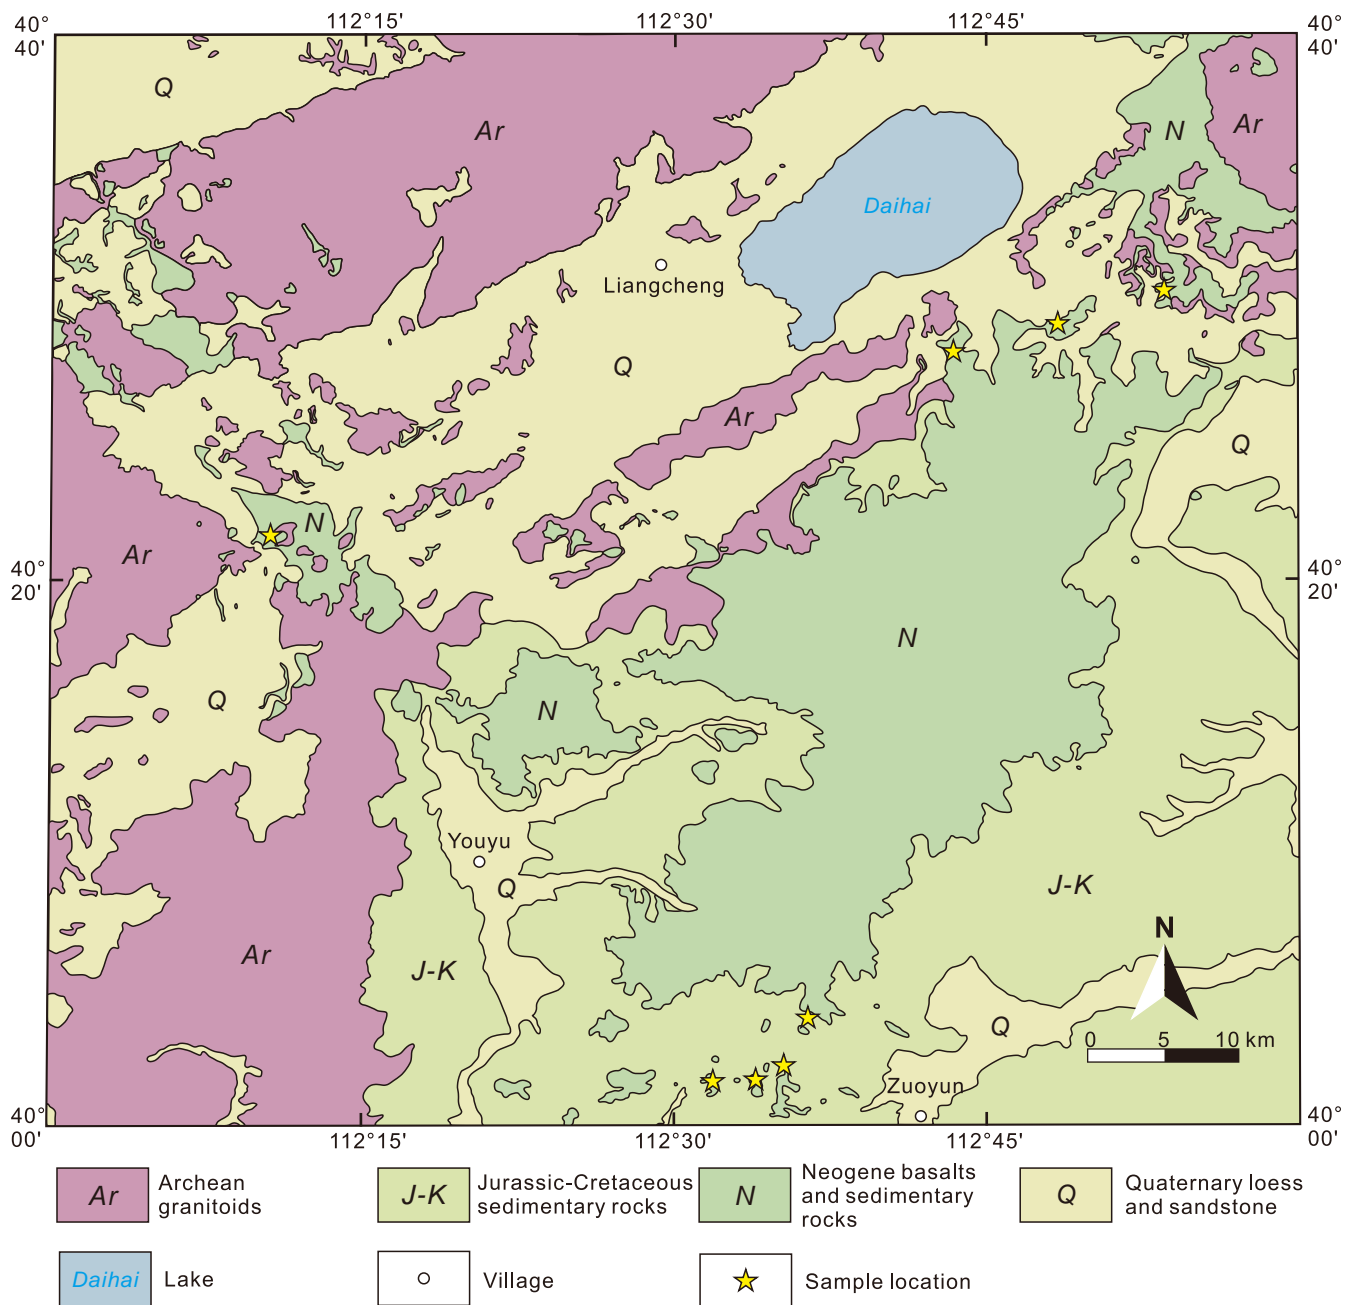

Fig. 2. Regional geological map of the Liangcheng volcanic field.

compositions were determined on carbon-coated polished sections using JXA-8100 electron microprobe at the Key Laboratory of Submarine Geosciences, Second Institute of Oceanography, Ministry of Natural Administration. The analyses were performed with an accelerating voltage of 15 kV, a 20 nA current, and beam diameters of 1–5 μm. Data were corrected using a modified ZAF (atomic number, absorption, fluorescence) correction procedure. Calibration standards were olivine (Mg), rutile (Ti), pyrope (Al), Cr_2O_3 (Cr), hematite (Fe), Mn_2O_3 (Mn), diopside (Si, Ca), jadeite (Na), and NiO (Ni). Peak counting times were 20 s and background counting times were 10 s on each side of the peaks. Internal standards (SPI olivine and diopside) were analyzed as unknown before the analyses, and the SPI olivine was also used as a secondary standard to check the olivine data accuracy. Analysis precision for measured contents >10% and > 0.5% are generally better than 1% and 5%, respectively, and for elements with contents <0.5 wt%, the precision may be less than 10%. The poor accuracy for elements with low

concentrations is attributed to the instrument's precision and inappropriate experimental conditions (low electric current and/or short signal acquisition time) (Lambart et al., 2022). In-situ trace-element analysis for the olivine grains was conducted using a 193 nm RESOlution S-155 laser-ablation system coupled to a Thermo iCAP RQ inductively coupled plasma mass spectrometer (LA-ICP-MS) at the State Key Laboratory of Geological Processes and Mineral Resources (GPMR), China University of Geosciences, Wuhan. The analyzed samples were ablated using a 40 μm spot size, 10 Hz repetition rate, and 4 J/cm² corresponding energy density. Helium gas (~400 ml/min) carrying the ablated sample aerosol was mixed with Argon gas (~800 ml/min) and a small amount of Nitrogen gas (~4 ml/min) as an additional diatomic gas to enhance sensitivity, before flowing into the ICP-MS. Repeated analyses of the USGS standards (BIR-1G, BHVO-2G, and BCR-2G) indicate precision and accuracy are both better than 10% for most analyzed elements. The measured trace elements were: Li, P, Ca, Sc, Ti, V, Cr, Mn, Co, Ni, and Zn.

The NIST glasses were used for correcting the signal drift. The isotope ^{29}Si was used as the internal standard in conjunction with the Si concentrations determined previously by EPMA. ICPMSDataCal software (Liu et al., 2010) was used for the off-line data selection, integration of background and analyte signals, time-drift correction, and quantitative calibration. Data for olivine, clinopyroxene, and feldspar can be found in Table S1.

3.2. Whole-rock geochemical analyses

Whole-rock major-element compositions were determined by the traditional X-ray fluorescence (XRF) method using a Shimadzu Sequential 1800 spectrometer at GPMR. The detailed procedures were described by Ma et al. (2012). According to the measured values of standard (GBW07105), the analytical uncertainties for most elements are generally less than 5%. Bulk rock trace-element compositions were acquired using an Agilent 7700e ICP-MS after acid digestion of the samples in high-pressure Teflon bombs at Wuhan SampleSolution Analytical Technology Co., Ltd., (WSSAT). Sample powder (200 mesh) was placed in an oven at 105 °C for drying of 12 h. Then, 50 mg sample powder was weighed and placed in a Teflon bomb, and 1.5 ml of HNO_3 and 1.5 ml of HF were added to the bomb, which was sealed in a steel jacket and heated to 190 °C in the oven for 48 h to completely dissolve the sample. After cooling, the Teflon bomb was opened and placed on a hotplate at 140 °C and evaporated to incipient dryness, and the 1 ml HNO_3 was added and evaporated to a second round of dryness. The resultant salt was redissolved by 1 ml of HNO_3, 1 ml of Milli-Q water, and 1 ml internal standard solution of 1 ppm In, and the Teflon bomb was resealed and placed in the oven at 190 °C for >12 h. The final solution was diluted to 100 g with a mixture of 2% HNO_3 for ICP-MS analysis. Analyses of four international standards (AGV-2, BHVO-2, BCR-2, and RGM-2) indicate that the analytical uncertainties for most trace elements are generally less than 5%. The detailed sample digestion procedure and the analytical precision and accuracy during ICP-MS analyses were the same as those described in Liu et al. (2008b). Whole-rock major and trace element data for samples and standards are listed in Table S2.

3.3. Sr–Nd–Pb–Hf isotopic analyses

Nine samples were selected for whole-rock Sr–Nd–Pb–Hf isotope analysis at the WSSAT. For the Sr–Nd isotopic analysis, approximately 200 mg of the sample powder was completely dissolved in HF-HClO$_4$ at 200 °C for one week. Sr and Nd were separated using conventional ion-exchange columns, and Nd fractions were further separated using HDEHP columns. The procedural blanks were 200 pg for Sr and 30 pg for Nd. The measured $^{87}Sr/^{86}Sr$ and $^{143}Nd/^{144}Nd$ ratios were normalized to $^{88}Sr/^{86}Sr = 8.3752$ and $^{146}Nd/^{144}Nd = 0.7219$, respectively. The measured values for the NBS987 standard yielded $^{87}Sr/^{86}Sr = 0.710243 \pm 0.000010$ (2SE, $n = 4$), and the GSB 04-3258-2015 standard yielded $^{143}Nd/^{144}Nd = 0.512441 \pm 0.000006$ (2SE, $n = 4$). The USGS reference materials BCR-2 and RGM-2 gave results of 0.704999 ± 0.000007 (2SE, $n = 1$) and 0.704143 ± 0.000008 (2SE, $n = 1$), respectively, for $^{87}Sr/^{86}Sr$ and 0.512640 ± 0.000006 (2SE, $n = 1$) and 0.512793 ± 0.000006 (2SE, $n = 1$), respectively, for $^{143}Nd/^{144}Nd$. These values are identical, within error of 0.03% of their recommended values (Thirlwall, 1991; Weis et al., 2006; Li et al., 2012, 2016a).

For Pb isotopic determination, the whole rock powder was dissolved in Teflon vials with purified HF + HNO_3 at 190 °C for >24 h and then separated using anion-exchange columns with diluted HBr and HCl as eluents. The procedural blank for Pb was 50 pg. Isotopic ratios were also determined using the Neptune Plus MC-ICP-MS. Repeated analyses of Pb isotopes for standard NBS981 yielded $^{208}Pb/^{204}Pb = 36.727 \pm 0.002$, $^{207}Pb/^{204}Pb = 15.500 \pm 0.001$, and $^{206}Pb/^{204}Pb = 16.942 \pm 0.001$ (2SE, $n = 3$). For the in-house Alfa Pb standard the values were $^{208}Pb/^{204}Pb = 37.851 \pm 0.002$, $^{207}Pb/^{204}Pb = 15.597 \pm 0.001$, and

$^{206}Pb/^{204}Pb = 17.917 \pm 0.001$ (2SE, $n = 3$). The USGS reference materials BCR-2 yielded results of $^{208}Pb/^{204}Pb = 38.741 \pm 0.001$, $^{207}Pb/^{204}Pb = 15.627 \pm 0.000$, and $^{206}Pb/^{204}Pb = 18.758 \pm 0.001$ (2SE, $n = 1$), and the RGM-2 yielded results of $^{208}Pb/^{204}Pb = 38.647 \pm 0.002$, $^{207}Pb/^{204}Pb = 15.621 \pm 0.001$, and $^{206}Pb/^{204}Pb = 18.933 \pm 0.001$ (2SE, $n = 1$). The measured standards and references were identical within the error of the recommended values (Baker et al., 2004; Weis et al., 2006).

For Hf isotopic analysis, approximately 200 mg of the powder was digested in Teflon bombs with a mixture of concentrated HNO_3 + HF and dried on a hot plate. This was followed by the addition of concentrated HNO_3, HF, and $HClO_4$ sealed in bombs and kept in an oven at 190 °C. After cooling, the Teflon bomb was opened, and 1 ml HNO_3 was added and evaporated to dryness. A modified ion-exchange single-column LN-Spec resin was used for Hf separation. The procedural blank for Hf was 50 pg. Mass discrimination correction was performed via internal normalization to a $^{179}Hf/^{177}Hf$ ratio of 0.7325. The in-house AlfaHf standard measured during analysis gave an average $^{176}Hf/^{177}Hf$ ratio of 0.282224 ± 0.000006 (2SE, $n = 5$), and the reference materials BCR-2 and RGM-2 yielded $^{176}Hf/^{177}Hf$ ratios of 0.282855 ± 0.000007 (2SE, $n = 1$) and 0.283010 ± 0.000007 (2SE, $n = 1$), respectively, which are within the range of the recommended values (Weis et al., 2007; Chen et al., 2013). The whole-rock Sr–Nd–Pb–Hf isotopic data are shown in Table 1.

4. Results

The olivine grains have forsterite contents [Fo = 100*Mg/(Mg + Fe)] varying from 64.7 to 86.5 (Fig. S2), and most of them are in equilibrium with the whole rock, assuming the Fe–Mg partition coefficient ($K_D = 0.30 \pm 0.03$) between olivine and melt (Fig. S2; Roeder and Emslie, 1970). Their CaO contents (0.1–0.26 wt%, Table S1) were slightly higher than those of typical mantle olivine (CaO < 0.1 wt%; Foley et al., 2013), together with the euhedral and subhedral crystal shapes, suggesting that they were precipitated from magmas instead of being xenocrysts. In addition, they have high Ni (0.07–0.40 wt%, corresponding to 534–3104 ppm) and Zn (99–244 ppm) and varied Mn (0.10–0.26 wt%, corresponding to 767–1990 ppm) concentrations with 100*Mn/Fe ratios of 0.53–1.85 and 10,000*Zn/Fe ratios of 9.15–17.6. It should be noted that except for the Ni concentrations, other trace elements (e.g., Ca, Mn) of olivine presented here are acquired through LA-ICP-MS as these elements have concentrations that are too low to have acceptable precision by EPMA (uncertainty >10%) when measured by routine analysis (see section 3), which is also suggested by the poor correlations between data from EPMA and LA-ICP-MS (Fig. S3). Clinopyroxenes are mainly diopside (Wo$_{36-48}$En$_{27-39}$Fs$_{6-18}$CaTs$_{8-21}$) (Fig. S2) and have TiO_2 contents of 0.20–3.21 wt%, Al_2O_3 contents of 3.41–9.89 wt%, and Mg$^{\#}$ values of 47.7–70.8. The compositions of feldspar vary from andesine to labradorite (An$_{38-65}$) (Fig. S2).

The Liangcheng basalts have SiO_2 contents of 45.2 to 49.0 wt%, and high contents of alkali elements ($K_2O + Na_2O$) (4.27–7.38 wt%) and belong to the alkaline series (Fig. 3A). These rocks display various MgO contents (5.69–9.54 wt%), low CaO (6.70–9.36 wt%) and MnO (0.12–0.16 wt%), and high Fe_2O_3T (10.1–12.2 wt%) contents with correspondingly high Fe/Mn ratios (59.2–81.1). The TiO_2 (1.77–2.43 wt%), Fe_2O_3T, and MnO contents are nearly invariant with decreasing MgO contents. The CaO/Al_2O_3 ratios positively correlate with the MgO contents for samples with MgO < 8 wt%, but show no obvious correlation for those with MgO ≥ 8 wt% (Fig. 3B). The Liangcheng basalts display ocean-island basalt (OIB) -type trace-element patterns, which are, enriched in large ion lithophile elements (LILEs) and light rare earth elements (LREEs) with positive anomalies in Nb, Ta, Sr, Ba, and negative anomalies in Th, and Pb (Fig. 4). These samples show radiogenic Sr isotopes ($^{87}Sr/^{86}Sr = 0.703924$–$0.705688$) and moderately depleted to slightly enriched Nd–Hf isotopes ($^{143}Nd/^{144}Nd = 0.512539$–$0.512861$, $^{176}Hf/^{177}Hf = 0.282824$–$0.282999$), with positive correlations in the

plot of $^{143}Nd/^{144}Nd$ vs. $^{176}Hf/^{177}Hf$ (Figs. 5A, B). They are distinct from Pacific MORB owing to their higher $^{207}Pb/^{204}Pb$ and $^{208}Pb/^{204}Pb$ compared to the standard $^{206}Pb/^{204}Pb$ and show similarities with Indian MORB (Figs. 5C, D).

5. Discussion

5.1. Alteration, contamination, and differentiation

The post-magmatic alteration effect on the compositions of the basalts is neglected because of the low LOI values (< 3 wt%, Table S2) and overall freshness in hand specimens and thin sections. This could be further assessed by the correlation between LILEs (e.g., Rb, Sr, Ba, and LREE) and high field strength elements (HFSEs) (e.g., Zr and Hf), as both group elements are incompatible during mantle partial melting or crystallization (Bédard, 2006), and positive correlations would be observed if they are only controlled by magmatic processes (Polat et al., 2002). In contrast, if the alteration were significant, the correlation would be disturbed because LILEs can be mobilized during alteration while HFSEs tend to remain immobile under similar conditions (Polat et al., 2002). The good correlation between the LILEs and HFSEs in the Liangcheng basalts suggests that the alteration was insignificant (Fig. S4), except for one sample (20GQZ-1) that may have suffered slightly alteration according to its petrological features (altered minerals and groundmass), the highest LOI (2.63 wt%) among collected basalts, and elevated Rb and Pb concentrations (Fig. S4).

Crustal contamination is also negligible because most of the studied basalts have trace element patterns similar to the enriched mantle-type OIB with remarkably positive Nb–Ta anomalies, negative Th and Pb anomalies, high Nb/U, Ce/Pb, and low Zr/Nb ratios, in contrast with the continental crust (Figs. 4, S5, Table S2; Rudnick and Gao, 2014). The lack of correlations between isotopes (Sr, Nd, Hf) and MgO is also inconsistent with crustal contamination (Fig. S5), as the continental crust is characterized by low MgO content, radiogenic Sr and unradiogenic Nd–Hf isotopic compositions (Liu et al., 2004).

The positive correlation between CaO and MgO contents implies the fractionation of clinopyroxene (Table S2). However, CaO variations may also be affected by source heterogeneity. Positive correlations between CaO and radio-isotopes ($^{143}Nd/^{144}Nd$, $^{176}Hf/^{177}Hf$) are observed for basalts with high MgO contents (≥ 8 wt%), suggesting that the variation of CaO for these basalts may be affected by mantle source heterogeneity rather than magma differentiation (Fig. S6). Except for CaO contents, CaO/Al_2O_3 ratios and Sc concentrations are primarily controlled by clinopyroxene; thus, their variations can be used to evaluate the effect of clinopyroxene fractionation. Positive trends exist among CaO/Al_2O_3, Sc, and MgO in the samples with MgO < 8 wt%, but no obvious correlations are presented in samples with MgO ≥ 8 wt%, indicating negligible clinopyroxene crystallization for high MgO samples (Figs. 3B, C). The generally positive correlation between Ni and MgO reflects olivine removal throughout magma differentiation because of the compatibility of Ni in olivine from the alkaline basalts (Fig. 3D). In addition, the absence of plagioclase phenocrysts and weak Eu anomalies (Eu/Eu* = 0.98–1.06, where Eu/Eu* = $Eu_N/(Sm_N*Nd_N)^{0.5}$; N, chondrite normalized) suggests that the plagioclase fractionation is minor (Fig. 4, Table S2). The consistent TiO_2 and Fe_2O_3T with decreasing MgO also indicate insignificant fractionation of Fe–Ti oxides (Table S2). These results suggest that the high-MgO samples may have only experienced olivine fractionation. This conclusion is consistent with previous studies on regional Cenozoic basalts (Liu et al., 2008a; Xu et al., 2017). To minimize the effects of mineral fractionation, we chose rocks with MgO ≥ 8 wt% to constrain their source lithologies and melting conditions.

5.2. Source lithology

Mineral (especially olivine) compositions (Sobolev et al., 2005; Herzberg, 2011; Foley et al., 2013) and whole-rock geochemical
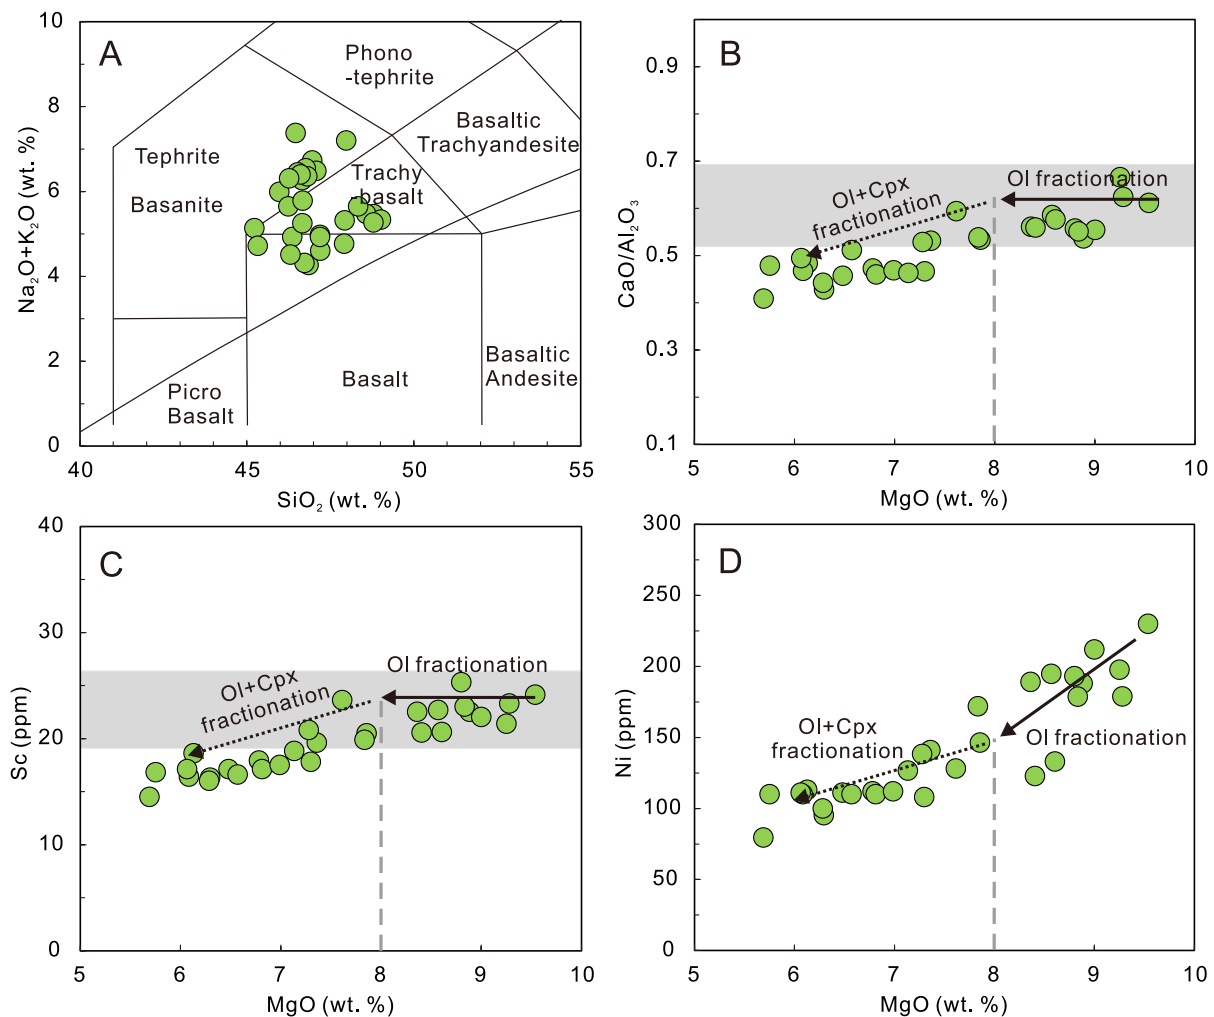

Fig. 3. (A) Total alkali ($Na_2O + K_2O$) vs. SiO_2 contents (Le Bas et al., 1986); CaO/Al_2O_3 ratios (B), Sc concentrations (C), and Ni concentrations vs. MgO contents (D).

contents (e.g., CaO contents, Herzberg, 2011) and ratios (Fe/Mn, Zn/Fe, FC3MS, FCKANTMS, Liu et al., 2008a; Le Roux et al., 2010; Yang and Zhou, 2013; Yang et al., 2019) have been proposed as useful tools to discriminate the source lithology of basalts. The olivine phenocrysts of the Liangcheng basalts display high Ni concentrations, and low Mn and Ca concentrations that are similar to olivine from typical pyroxenite-derived basalts, such as those from Koolau and Loihi, suggesting crystallization from pyroxenite melts (Figs. 6A, B, C; Sobolev et al., 2005; Herzberg, 2011; Foley et al., 2013; Shi et al., 2022). However, recent experimental studies showed that Ni and Mn partition coefficients between olivine and melt are related to pressure and temperature conditions, which may cause Ni enrichment and Mn depletion in melt derived from high-pressure melting of a peridotite source (Matzen et al., 2017). This weakness can be improved by using additional indexes such as transition elements and their ratios (Mn, Zn, Fe, Zn/Fe, Mn/Zn, and Mn/Fe; Howarth and Harris, 2017). The Zn/Fe, Mn/Zn, and Mn/Fe ratios for olivine grains of Fo > 80 from Liangcheng basalts straddle from the field of pyroxenite-peridotite mixed to pyroxenite source, suggesting a pyroxenite-bearing mantle source lithology (Figs. 6D, E, F). In addition, the whole-rock TiO_2 and MnO contents of Liangcheng basalts show little variation during magma evolution and thus can be used to discriminate the source lithology via comparison with experimental data (Table S2). The studied basalts are characterized by high TiO_2 contents and all fall into the field of pyroxenite (both silica-excess and silica-deficient) melts (Fig. 7A). Besides that, a whole-rock major composition-based indicator of FC3MS ($FeO/CaO-3MgO/SiO_2$) proposed by Yang and Zhou (2013)

has been suggested as useful to discriminate the source lithology of basalt. Yang and Zhou (2013) compiled experimental and natural data of peridotite and pyroxenite melts and suggested that the upper limit of FC3MS value for peridotite melts is 0.65, and higher FC3MS value for peridotite melts can only be reached by substantial clinopyroxene fractionation (> 30%), which is unrealistic for the Liangcheng basalts with high MgO contents ($\geq$ 8 wt%) because they only experienced olivine fractionation. Therefore, the high FC3MS values (0.49–0.77) of the Liangcheng basalts may suggest contributions from pyroxenite melts (Fig. 7B). In addition, the recently proposed parameter, FCKANTMS (ln (FeO/CaO)-0.08*ln(K_2O/Al_2O_3)-0.052*ln(TiO_2/Na_2O)-0.036*ln($Na_2O/$ K_2O)*ln(Na_2O/TiO_2)-0.062*(ln(MgO/SiO_2))^3–0.641*(ln($MgO/$ SiO_2))^2–1.871*ln(MgO/SiO_2)-1.473) is also a useful index in discriminating the source lithology of basalt, and olivine fractionation only causes limited variation (0–0.15) of this value (Yang et al., 2019). The Liangcheng basalts have much higher FCKANTMS (0.42–0.64) than those for peridotite melts (< 0.1) as shown in Figs. 7C, D, also indicating a major contribution from pyroxenite melting. The above evidence collectively suggests a pyroxenite-bearing mantle source lithology for the Liangcheng basalts.

Discriminating the nature of the pyroxenite is of great importance before we gain knowledge about the melting conditions because different types of pyroxenite may have various mineral modes, phase relations, and melting behavior (Lambart et al., 2016). The nature of pyroxenite could be identified using whole-rock compositions since different types of pyroxenites (silica-deficient and silica-excess) would
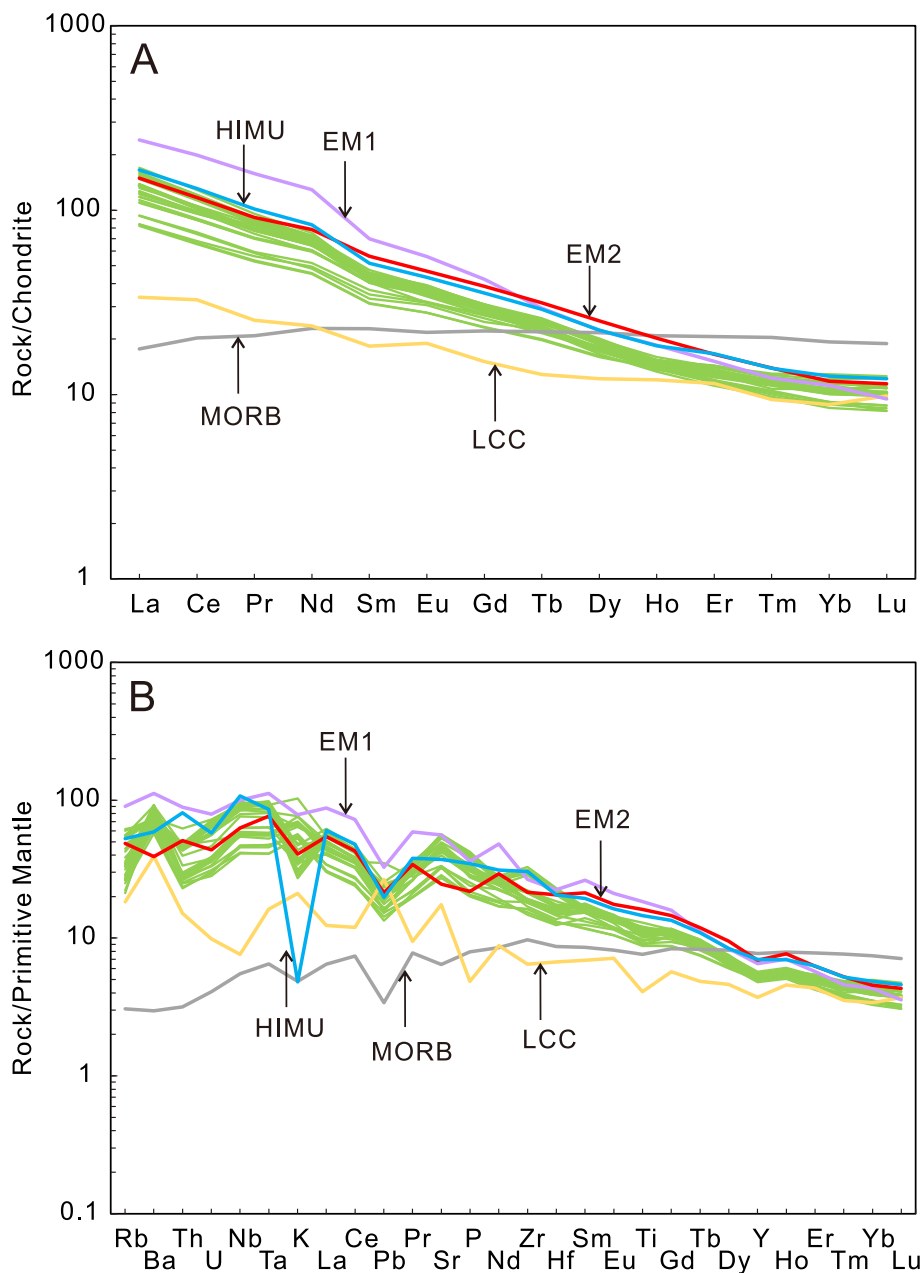

Fig. 4. (A) Chondrite-normalized REE patterns; (B) primitive mantle-normalized spider diagrams. Normalizing data for the chondrite and primitive mantle are from Sun and McDonough (1989) and McDonough and Sun (1995), respectively. The data source for the average MORB is from Gale et al. (2013), the average HIMU, EM1, and EM2 are from Kawabata et al. (2011), Willbold and Stracke (2006) and Workman et al. (2004), respectively, and the lower continental crust (LCC) is from Rudnick and Gao (2014).

generate melts with contrasting compositions (Lambart et al., 2013). Here, we adopted a pseudo-ternary sub-projection consisting of a whole array of major elements to provide insights into the nature of the pyroxenite in the source of the studied basalts (Fig. 8). It clearly shows that the Liangcheng basalts with high MgO contents (≥ 8 wt%) are deficient in SiO_2 and similar to experimental melts of silica-deficient pyroxenite, and addition of olivine (to recover the primary melt composition) would not drive these basalts into fields of silica-excess pyroxenite melts. Although experiments proposed that reacted melts between MORB-eclogite (silica-excess pyroxenite) partial melts and fertile peridotite could generate basalts with low silica and high alkali that are similar to natural alkaline basalts (Mallik and Dasgupta, 2012), we suggest such a scenario is not the case for the Liangcheng basalts since these basalts exhibit much lower TiO_2 contents at similar MnO contents, indicating inconsistency with the reacted melts (Fig. 7A). As a consequence, we suggest that the pyroxenite in the source of the Liangcheng basalts is silica-deficient pyroxenite.

5.3. Melting conditions of the pyroxenite-bearing asthenosphere

Preferential melting of non-peridotite source lithology extracts latent heat from the ambient mantle and further facilitates the melting process, but suppresses the melting of the surrounding peridotite (Oliveira et al., 2021). Consequently, the mass contribution of such low-solidus lithology (e.g., pyroxenite) to the melt overweighs its proportion in the mantle (Lambart et al., 2016). The complicated chemical and thermal processes make it difficult to recover the melting condition based on the bulk major-element compositions of primary magma acquired by reverse methods for single-source lithology (e.g., the addition or removal of olivine, Lee et al., 2009; Herzberg, 2011). Herein, we employed a forward-modeling method based on whole-rock incompatible trace-element compositions using REEBOX PRO (Brown and Lesher, 2016) to explore the melting conditions and source characteristics.

REEBOX PRO is a software package that can simulate the adiabatic decompression melting of heterogeneous mantle sources containing anhydrous peridotite (lherzolite), hydrous peridotite (lherzolite),
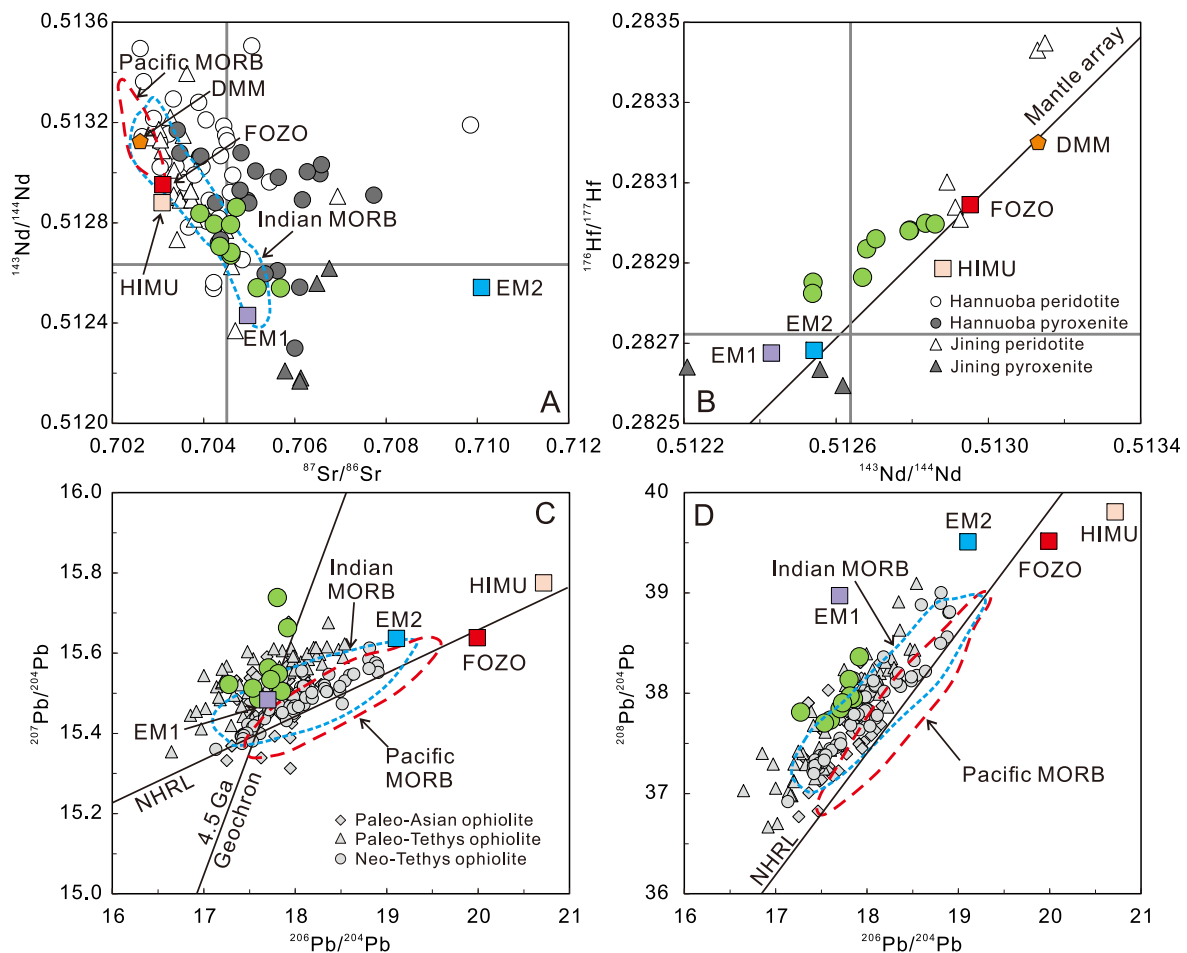

Fig. 5. Whole-rock (A) $^{143}Nd/^{144}Nd$ vs. $^{87}Sr/^{86}Sr$; (B) $^{176}Hf/^{177}Hf$ vs. $^{143}Nd/^{144}Nd$; (C) $^{207}Pb/^{204}Pb$ vs. $^{206}Pb/^{204}Pb$; (D) $^{208}Pb/^{204}Pb$ vs. $^{206}Pb/^{204}Pb$ diagrams. The areas for Indian MORB and Pacific MORB are taken from Xu and Zheng (2019), and data for FOZO (Cook-Austral), HIMU (St. Helena), EM1 (Pitcairn), and EM2 (Samoa) are from the GEOROC database (http://georoc.mpch-mainz.gwdg.de/georoc/). The average Sr, Nd, Pb, and Hf isotopic compositions for depleted-MORB mantle (DMM) are from Workman and Hart (2005) and references therein. The data of ophiolites from the Neo-Tethys Ocean, Paleo-Tethys Ocean, and Paleo-Asian Ocean are compiled in Liu et al. (2015c). The mantle xenoliths from Hannuoba and Jining are compiled in Zhao et al. (2021).

pyroxenite (three types: G2, MIX1G, and KG1 pyroxenite) and/or residual harzburgite (Brown and Lesher, 2016; Brown et al., 2020). The key model inputs include the mantle potential temperature, lithospheric thickness, trace element abundances, isotopic composition, and water content of the source rocks. Assuming that all specified lithologies are in thermal equilibrium rather than chemical equilibrium, the program uses thermodynamic and experimental constraints to quantify their polybaric productivities (dF/dP) at discrete decompression steps (per 0.01 GPa) between the deepest solidus and the base of the lithosphere. The mineral model parameterizations of the solidus are based on experimental constraints and thermodynamic modeling using Perple_X (Connolly, 1990, 2005). Using experimentally constrained mineral modes, melting modes, and either temperature-dependent or static mineral-melt partition coefficients, the model then calculates the compositions of instantaneous melts generated by the incremental batch melting of each lithology during each decompression step. For each lithology, instantaneous melts are mixed along the melting column to provide a "column-accumulated" melt composition at the top of the melting column. Finally, the bulk (aggregate) igneous crust thickness and composition are calculated by pooling all column-accumulated melts derived from all the lithologies (pooled melts) (Brown et al., 2020).

Before the modeling, we need to point out that the factor of CO_2 was not taken into account in the software, which may affect the results because the carbonated mantle source has been proposed to play an important role in forming the Cenozoic alkaline basalts in Central-East

Asia (Zeng et al., 2010, 2021; Yang et al., 2012; Sakuyama et al., 2013; Huang et al., 2015; Li et al., 2017; Wang et al., 2017; Xu et al., 2018; He et al., 2019b; Cai et al., 2022; Zou et al., 2022). To explore whether CO_2 is involved in the mantle source of the Liangcheng basalts, we used a SiO_2 vs. CaO diagram for discrimination (Herzberg and Asimow, 2008, Fig. S7). The theory behind this method lies in the fact that CO_2-bearing basalts are usually characterized by much lower SiO_2 and higher CaO than CO_2-free basalts (Herzberg and Asimow, 2008). The results show that the Liangcheng basalts plot in the region of CO_2-free basalts, suggesting that the impact of CO_2 on the studied basalts was minor (Fig. S7). This inference is supported by evidence that the negative anomalies in Zr–Hf and Ti, which are typical features of CO_2-bearing basalts, are not observed in the studied samples (Zeng et al., 2010). Although we could not rule out the possibility that CO_2 had once been involved in the source region, for which case the melts gradually evolved from carbonatitic melt to carbonate silicate melt and eventually to alkaline basalts (Xu et al., 2020 and references therein), we suggest that in this situation the effect of CO_2 on the composition of the basalts has been strongly diluted and therefore has an insignificant influence on the final melt compositions.

After evaluating the CO_2 impact, we conducted our modeling using the REEBOX PRO software. Four main controlling factors were considered in the modeling: (1) mantle potential temperatures, (2) source water content, (3) source compositions (lithological proportions), and (4) final depths of melting (lithosphere-asthenosphere boundary). Grid
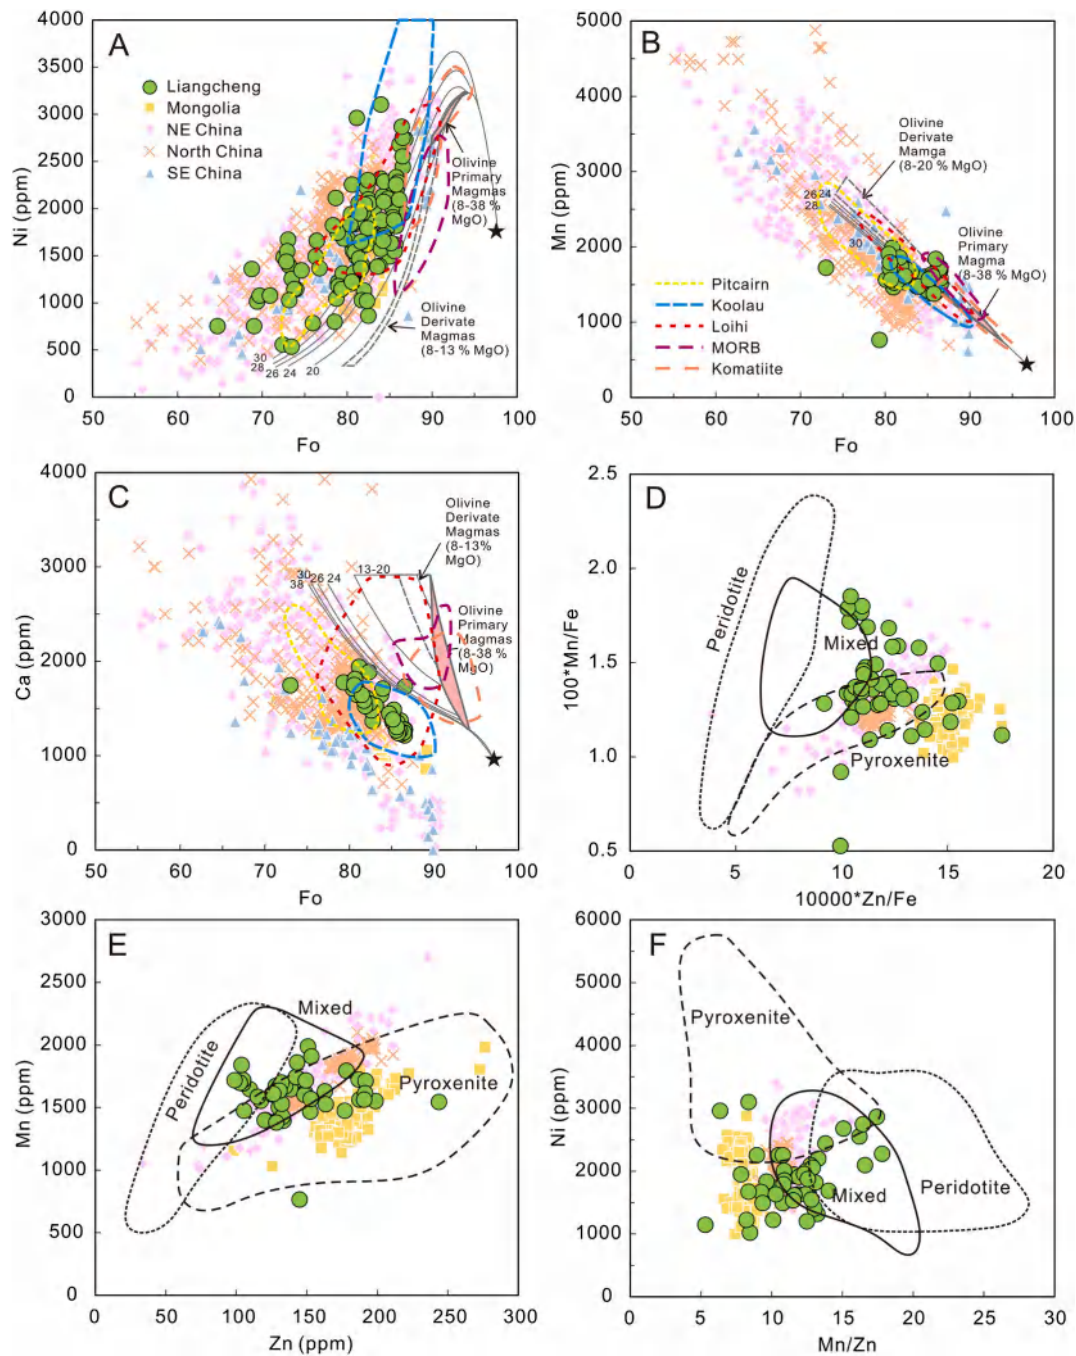

Fig. 6. Ni concentrations (A), Mn concentrations (B), and Ca concentrations (C) vs. Fo for olivine grains in the Liangcheng basalts; (D) 100*Mn/Fe vs. 10,000*Zn/Fe ratios, (E) Mn vs. Zn concentrations and (F) Ni concentrations vs. Mn/Zn ratios diagrams for Liangcheng olivine phenocrysts. Olivine Ni data plotted in (A) is from EPMA, while the Mn and Ca data plotted in (B) and (C) are acquired by LA-ICP-MS. The compositions of olivines crystallized from peridotite melts calculated by Herzberg (2011) are shown for comparison. The calculation was based on a fertile peridotite source with Ni of 1,964 ppm, Ca of 24,657 ppm, and Mn of 1,007 Mn. The calculated olivines are for both primary magmas and derivative magmas produced by olivine fractionation. The filled fields are for calculated olivines of the primary magmas. The other numbered lines and fields are for calculated olivines from derivative magmas with different MgO contents (Herzberg, 2011). Fields for olivines that have been interpreted to be derived from pyroxenite, peridotite, and pyroxenite-peridotite mixed source are from Howarth and Harris (2017) and references therein, and for olivine from Pitcairn, Koolau, Loihi, MORB, and Komatiite are from Shi et al. (2022) and references therein. Data for olivine phenocrysts in Cenozoic alkaline basalts from Mongolia (Zhang et al., 2021), NE China (Chen et al., 2015a; Wang et al., 2015; Zhang and Guo, 2016; Pang et al., 2019; Liu et al., 2022), North China (Xu et al., 2012b; Liu et al., 2015b; Li et al., 2016b; Xu et al., 2017; Hong et al., 2020, 2021), and SE China (Sun et al., 2017; Zeng et al., 2017) are illustrated in Table S4.

research was then carried out to find a combination of parameters when the resultant melt composition best matched the studied basalts. The effects of a single parameter on the compositions of the resulting melts are shown in Fig. 9. After grid inspection, the best-fit combination appears to be 80% lherzolite +20% silica-deficient garnet pyroxenite in the source, a final melting depth of ~2 GPa (corresponding to a lithospheric thickness of ~66 km), ~1380 °C mantle potential temperature, and ~500 ppm source water content in the source (Fig. 10). Note that the silica-deficient pyroxenite here is KG1. In addition to KG1, the other silica-deficient pyroxenite incorporated in the software, MIX1G, has also
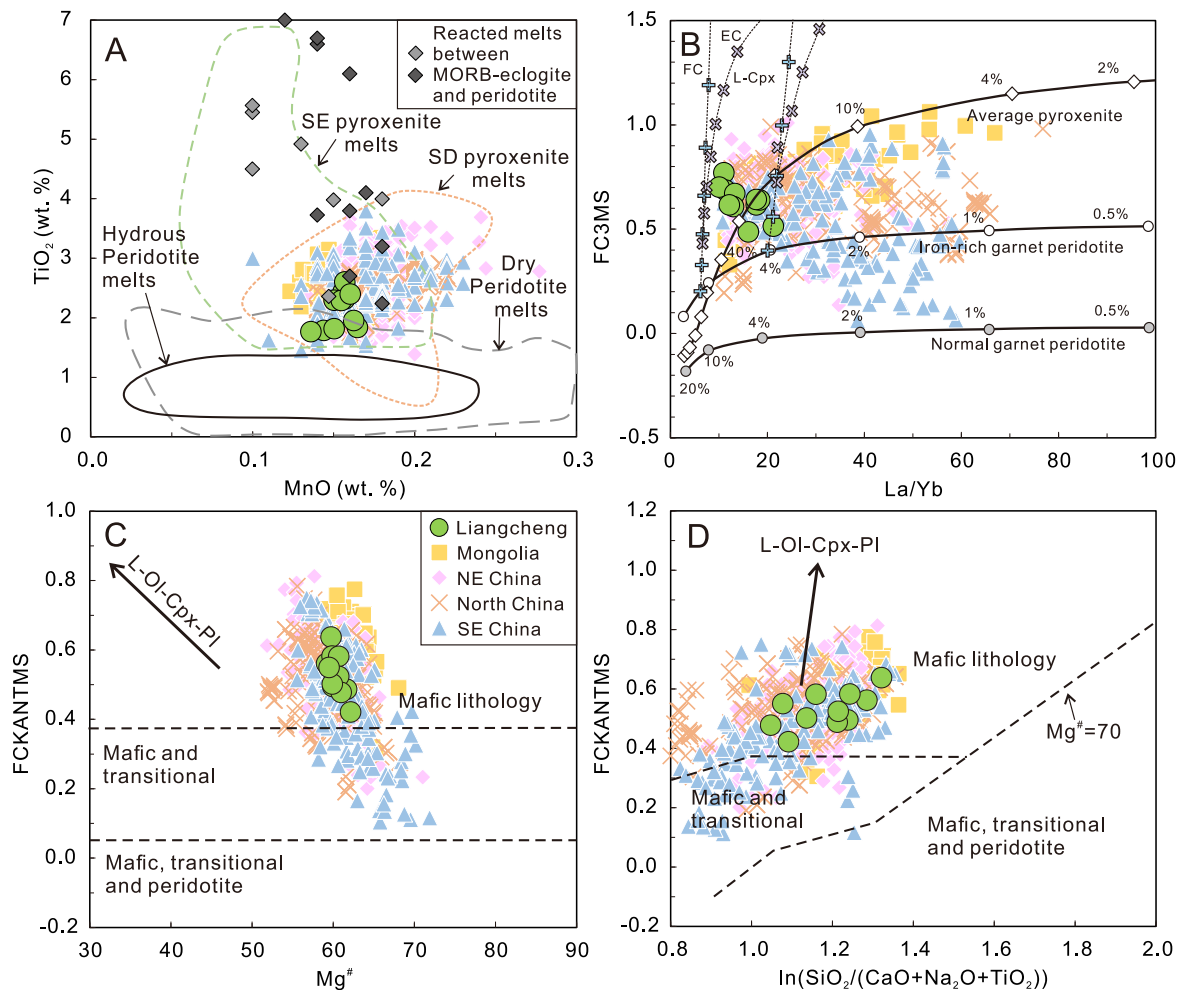

Fig. 7. (A) Whole-rock TiO$_2$ vs. MnO contents diagram. Sources of experimental data are identical to Liu et al. (2008a), and Ma et al. (2016). Reacted melts between MORB-eclogite and peridotite are from Mallik and Dasgupta (2012). The dark grey squares represent reacted melts obtained from the mixed runs while the light grey squares point to reacted melts acquired from the layered runs; (B) FC3MS values vs. La/Yb ratios. Variations of La/Yb ratios for experimental peridotite and pyroxenite melts are calculated through the batch melting model of Yang and Zhou (2013). The dashed lines with blue and purple cross represent Cpx fractional and equilibrium crystallization (FC and EC) by 10 wt% increments each step (Yang and zhou, 2013); FCKANTMS values vs. whole-rock Mg number (Mg$^{\#}$) (C) and ln (SiO$_2$/(CaO + Na$_2$O + TiO$_2$)) (D) (Yang et al., 2019). All plotted basalts have high MgO contents (≥ 8 wt%) and plot on the CO$_2$-free side in the CaO vs. SiO$_2$ diagram (Fig. S7). Data for basalts from Mongolia (Barry et al., 2003; Chuvashova et al., 2007; Savatenkov et al., 2010; Hunt et al., 2012; Yarmolyuk et al., 2015; Zhang et al., 2021), NE China (Chen et al., 2007; Chuvashova et al., 2007; Ho et al., 2008; Yan and Zhao, 2008; Zou et al., 2008; Xu et al., 2012a; Ho et al., 2013; Chen et al., 2015b; Wang et al., 2015; Yu et al., 2015; Guo et al., 2016; Zhang and Guo, 2016; Togtokh et al., 2019; He et al., 2019b; Pang et al., 2019; Lei et al., 2020), North China (Tang et al., 2006; Chen et al., 2007; Liu et al., 2008a; Chen et al., 2009b; Zhang et al., 2009; Zeng et al., 2010, 2011, 2021; Wang et al., 2011; Xu et al., 2012b, 2017; Sakuyama et al., 2013; Hong et al., 2020; Zou et al., 2022), and SE China (Zou et al., 2000; Ho et al., 2003; Zeng et al., 2013; Li et al., 2015, 2016c, 2020; Liu et al., 2016; Sun et al., 2017; Yu et al., 2019) are listed in Table S5. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

been considered. It can be observed that the results yielded by the MIX1G model show similar variations to those of the KG1 model when changing the parameters during modeling (Fig. S8). The best-fit model acquired using MIX1G as the end member shows identical final melting pressure and water content but a higher proportion of pyroxenite in the source and lower melting temperature than the KG1 model (Fig. 10). The best-fit conditions given by the MIX1G model do not fit well with the Liangcheng basalts compared to the KG1 model, which suggests MIX1G may not be an appropriate candidate. Such a result indicates that a pyroxenite with a high proportion of relatively refractory components, like KG1, is needed in the source of Liangcheng basalts because KG1 is a mixture of peridotite and pyroxenite and contains fewer fusible components than MIX1G (Kogiso et al., 1998). The estimated melting pressure and temperature align well with those calculated by whole-rock compositions (1384 ± 17 °C and 2.2 ± 0.2 GPa) (Figs. 11, S9; Lee et al., 2009; Herzberg, 2011), and the predicted water content approximates

those given by the minerals and whole-rock chemistry (550–759 ppm, see text in Supplemental Material, Figs. S10, S11, and Table S3), implying that our model is reliable. The melting temperature (~1380 °C) is significantly higher than the xenolith-based temperatures of the regional lithospheric mantle (< 1000 °C; Chen et al., 2001; Huang and Xu, 2010; Zhao et al., 2021), suggesting an asthenospheric origin. Since lithosphere may act as a passive mechanical barrier to continuous upwelling of the asthenosphere, the estimated final melting depth can be approximately treated as the melting pressure of these basalts (Niu et al., 2011). It should be noted that the melting pressure (~2 GPa, corresponding to the depth of ~66 km) is slightly lower than the regional lithospheric thickness as constrained by geophysical observations (~80 km, Chen et al., 2009a; Huang et al., 2009), which may be attributed to lithospheric thickening by asthenospheric thermal decay after basalt formation (Xu et al., 2004).
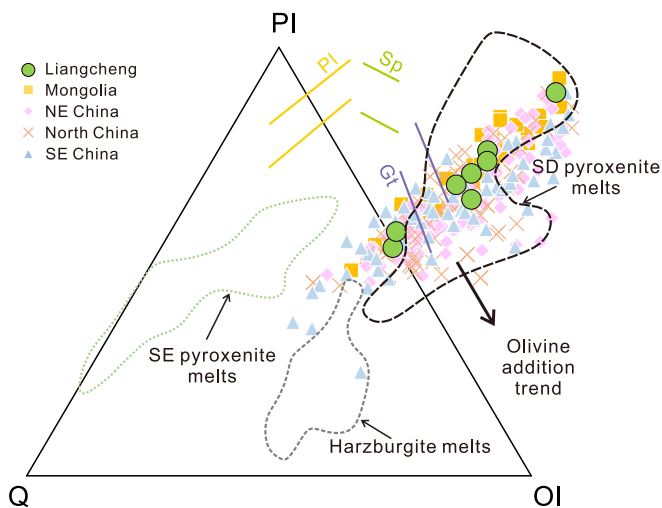

Fig. 8. Pseudoternary sub-projections for the Liangcheng basalts that only experienced olivine fractionation (Tormey et al., 1987; Grove, 1993). The predicted plagioclase (Pl), spinel (Sp), and garnet (Gt) lherzolite multiple saturation points (MSPs) as a function of increasing pressure from 1 atm to 4.0 GPa are also shown for comparison. Pl and Sp lherzolite MSPs are calculated based on the model of Till et al. (2012) and the calculation of Gt lherzolite MSPs is according to Grove et al. (2013). The pressure range for the calculation of Pl, Sp, and Gt lherzolite MSPs is 1 atm to 1.4 GPa, 1.4 to 2.4 GPa, and 2.4 to 4GPa, respectively. Mg# = 0.73, NaK# = 0.283 and 0.515, P$_2$O$_5$ = 0.7 wt% were used for the calculation. The three segments of each trend show compositional change of MSPs for Pl, Sp, and Gt lherzolite facies with increasing pressure. Data for experimental melts from silica-excess (SE) and silica-deficient (SD) pyroxenites as well as harzburgite are compiled in Liu et al. (2008a), and Ma et al. (2016). Data for basalts from Mongolia, NE China, North China, and NE China are shown in Table S5, and data sources are the same as those in Fig. 7.

5.4. Recycled components in the mantle source

It is widely accepted that recycled components were introduced in the mantle source of the Cenozoic basalts in Central-East Asia via subduction or delamination, and various types of recycled materials have been identified using geochemical and isotopic tools. These recycled components include continental crust, oceanic crust (both the upper and lower oceanic crust), and sediment (with or without carbonate) (Zeng et al., 2011; Xu et al., 2012a; Liu et al., 2015a, 2015b; Li et al., 2017). The Liangcheng basalts show positive Nb–Ta and negative Pb anomalies, in contrast with the continental crust (Rudnick and Gao, 2014). Instead, they are characterized by high Ce/Pb and Nb/U ratios, indicating the involvement of igneous oceanic crust. This is because subducted igneous oceanic crusts usually have high Nb/U and Ce/Pb ratios due to the preferential release of U and Pb relative to Nb and Ce during slab dehydration (Stracke et al., 2003). In addition, the absence of positive europium anomaly and positive correlation between Eu/Eu* and SiO$_2$ in the Liangcheng basalts suggest insignificant plagioclase accumulation in the source, thus ruling out the possibility of the involvement of lower oceanic crust (cumulate gabbro) in the source because lower oceanic crust contains abundant plagioclase and has high SiO$_2$ contents and relatively higher Sr, Eu concentrations than similarly incompatible elements (Xu et al., 2012a). Besides that, these basalts display enriched mantle-type OIB trace-element patterns and radiogenic Sr isotopic compositions, which may imply the incorporation of sediments into their source (Plank and Langmuir, 1998; Chauvel et al., 2008). To discriminate the types of incorporated sediments, we carried out quantitative modeling using trace elements and isotopic systematics (Fig. 12). We chose the depleted-MORB mantle (DMM), altered oceanic crust, and several kinds of sediments as endmembers; it should be noted that we did not consider carbonate-bearing sediments because carbonate plays a minor role in the source of the Liangcheng basalts as we discussed in

section 5.3. The modeling results suggest that both pelagic and terrigenous sediments were involved in the mantle source of the Liangcheng basalts (Fig. 12). As a result, we conclude that recycled oceanic crust, pelagic and terrigenous sediments collectively contributed to the formation of Liangcheng basalts. These recycled enriched components melted and reacted with the ambient peridotite to form a silica-deficient pyroxenite-bearing mantle domain, which acted as a source lithology for the studied basalt.

The Central-East Asian continent has experienced multiple subduction events during the Phanerozoic (Windley et al., 2010). These subductions involve the Paleo-Tethys oceanic crust and subsequent deep subduction of the Yangtze continental crust (> 200 Ma; Wu et al., 2009), the Paleo-Asian oceanic crust (540–200 Ma; Wan et al., 2018; Jing et al., 2022), the Mongol-Okhotsk oceanic crust (> 120 Ma; Kravchinsky et al., 2002; Van der Voo et al., 2015), and the (Paleo-) Pacific oceanic crust (< 180 Ma; Ma and Xu, 2021 and references therein). Discriminating the origin of recycled components is difficult because of the cumulative effects of different tectonic events. However, we compiled olivine chemistry, whole-rock geochemical and isotopic data of Cenozoic alkaline basalts from Central-East Asia (including NE China, North China, SE China, and Mongolia; Tables S4, S5) and we found that these basalts not only have similar source lithology but also show broadly overlapping isotopic compositions (Figs. 6, 7, 8, 12), suggesting that their mantle sources may share the same origins. Consequently, we propose that subducted oceanic crusts and sediments from different subduction episodes introduced various recycled components into the asthenospheric mantle. After long periods of mantle convection and mixing, recycled components of different origins are dispersed and may serve as mantle sources for the Liangcheng basalts as well as other Cenozoic alkaline basalts in Central-East Asia. We suggest that this scenario might explain the wide similarities in the source lithology and isotopic compositions of these basalts (Figs. 6, 7, 8, 12).

5.5. Melting mechanism of the Liangcheng basalts and its implication for the generation of intraplate basaltic magmatism in Central-East Asia

Cenozoic alkaline basalts beyond the BMW have been previously interpreted as derived from localized asthenospheric upwelling due to lithospheric rifting or delamination (Barry et al., 2003; Hunt et al., 2012), large-scale convection related to mantle plume (Johnson et al., 2005), or subduction of the Pacific plate or India-Eurasia collision (Li et al., 2018; Chen and Faccenda, 2019). The Liangcheng basalts are located in the North China Craton, which experienced craton destruction during the Mesozoic (Zhu and Xu, 2019; Wu et al., 2019). Large-scale extension structures, lithospheric delamination or rifting, and associated magmatism occurred during this period (Ma and Xu, 2021), much earlier than the formation of the Cenozoic basalts. Therefore, asthenospheric upwelling triggered by lithospheric rifting or delamination is unlikely in the studied basalts. For the mantle plume hypothesis, the relatively low calculated mantle potential temperatures (<1400 °C), the absence of geophysical observations and geological and petrological evidence, such as positive thermal anomalies, progressive age migration, radiant mafic dykes, or high-Mg# picrite, show no signs for the presence of a mantle plume beneath the studied area. As a consequence, the mantle plume model is not a candidate. Recently, direct mantle melting induced by subduction of the Pacific slab (Xu et al., 2018; Chen and Faccenda, 2019) or India-Eurasia collision (Li et al., 2018; Zhang et al., 2021) has been frequently suggested to explain the formation of widespread Cenozoic basalts in Central and East Asia. However, the Liangcheng area is away from the western edge of the subducted Pacific plate, as revealed by seismic images (Fig. 1B; Huang and Zhao, 2006), and can hardly be reached by mantle flow induced by the India-Eurasia collision because of the obstruction of the thick Ordos lithosphere (Yu et al., 2021). As a result, these basalts are unlikely to be directly linked to these two subduction events. Based on the above discussion, we suggest that an alternative melting mechanism is
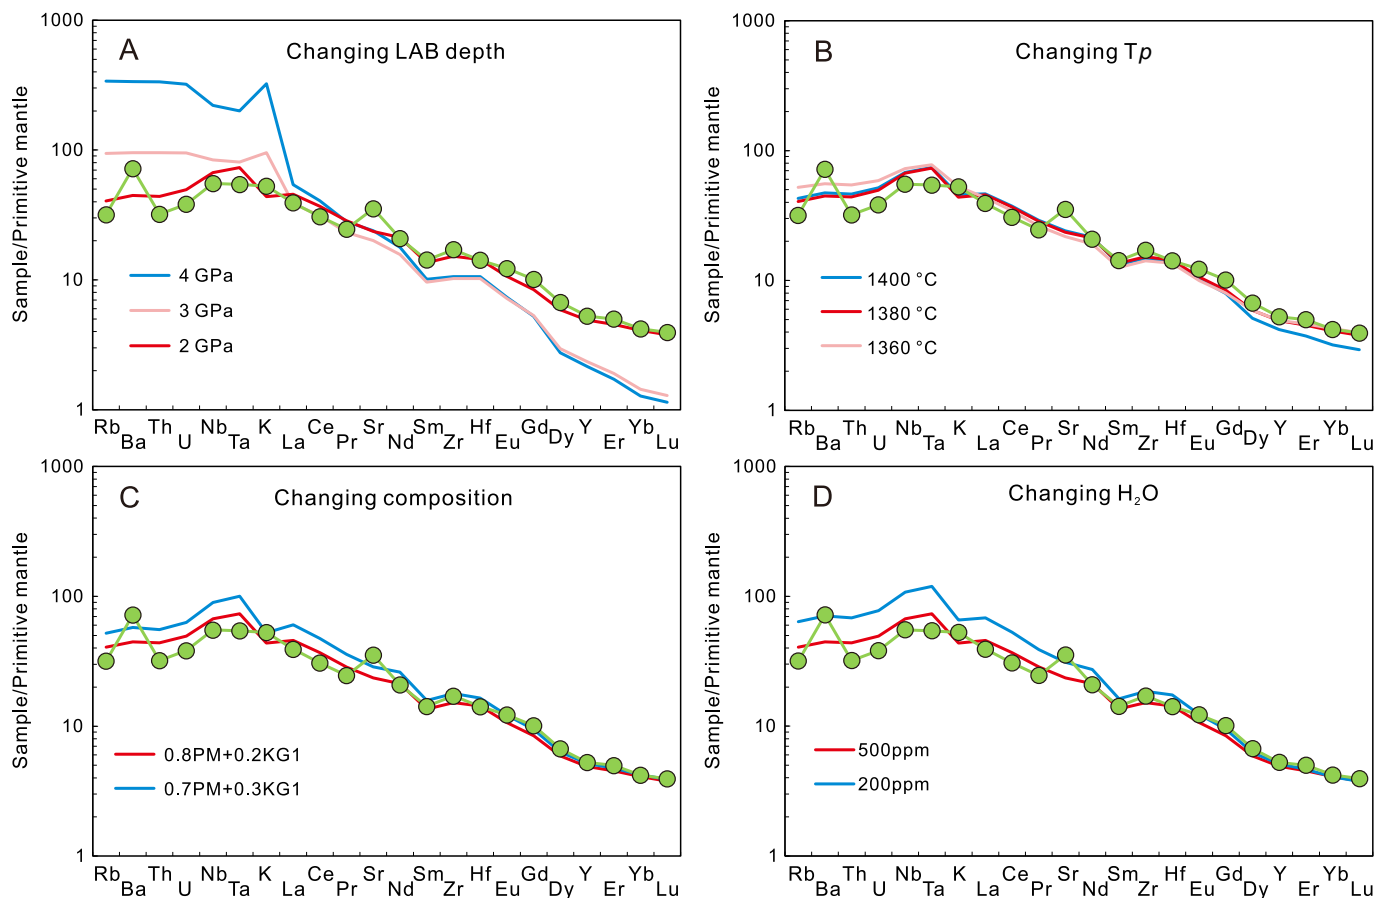

Fig. 9. Effects of mantle potential temperature, water contents, source lithologies, and final depth of melting (lithosphere-asthenosphere boundary, LAB) on the modeled melts. Also plotted is the average composition of the Liangcheng basalts (MgO ≥ 8 wt%). (A) the controlled parameters are source water content (500 ppm), source lithologies (80% PM + 20% KG1), potential temperature (1380 °C) and final melting pressure (2 GPa); (B) the controlled parameters are source water content (500 ppm), source lithologies (80% PM + 20% KG1) and final melting pressure (2 GPa); (C) the controlled parameters are source water content (500 ppm), potential temperature (1380 °C) and final melting pressure (2 GPa); (D) the controlled parameters are source lithologies (80% PM + 20% KG1), potential temperature (1380 °C) and final melting pressure (2 GPa). PM: primitive mantle (McDonough and Sun, 1995), KG1: silica-deficient pyroxenite (inserted in the REEBOX PRO program, Brown and Lesher, 2016). Abbreviations: Tp, potential temperature; LAB, lithosphere-asthenosphere boundary. The final melting depth is controlled by the lithospheric thickness and can be approximated to the thickness of the LAB (Niu et al., 2011). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

required to account for the generation of these basalts.

Edge-driven convection due to steps in the lithospheric structure/thickness combined with plate movement could be a feasible mechanism to explain the origin of the Liangcheng basalts. The lithosphere in the study area probably thinned before the basalt eruption based on the compositional transition from Mesozoic basalts to Cenozoic basalts (Guo et al., 2014). This inference is supported by the absence of garnet-bearing xenoliths (Zhao et al., 2021), the calculated low melting pressure of our samples and regional xenolith-bearing basalts (Xu et al.,2017), and the present lithospheric thickness determined by surface wave tomography (~80 km; Chen et al., 2009a; Huang et al., 2009). In addition, S-receiver function images have revealed that the lithospheric thickness of the western NCC is characterized by significant lateral variations, which is 200 km in the Ordos block and sharply thinned to 80 km in the Yinchuan-Hetao and Shaanxi-Shanxi rift areas over a lateral distance of <200–400 km (Chen et al., 2009a). Such abrupt and significant changes in lithospheric thickness, combined with the disturbance from deep subduction of the Pacific plate, would efficiently cause edge-driven convection of the asthenosphere beneath the NCC, especially if the viscosity of the asthenospheric mantle was lowered by melts and volatiles released from the Pacific plate, as has been suggested by a recent numerical modeling study (Sun and Liu, 2023). Since the Liangcheng area locates in the joint of the Yinchuan-Hetao and

Shaanxi-Shanxi rift system with a thin lithosphere and is adjacent to the Ordos block, it is, therefore, in a propitious tectonic situation to trigger edge-driven convection. In this case, decompression melting of the asthenospheric mantle would occur when mantle convection drives fusible mantle domains from areas with relatively thick lithosphere to those that have thin ones.

The Liangcheng basalts share many similarities with many other Cenozoic alkaline basalts in Central-East Asia, especially those with high MgO (≥ 8 wt%) and plotted on the CO_2-free side in the CaO vs. SiO_2 diagrams (Fig. S7). These similarities include: 1) the geological distribution patterns in which these basalts are preferentially developed along deep major faults or weak zones between stable blocks (Fig. 1A); 2) they all have silica-deficient pyroxenite in the source (Figs. 6, 7, 8); 3) they yield low melting pressure (Fig. 11, <3 GPa); 4) similar recycled components such as oceanic crust and sediment (both pelagic and terrigenous) existed in their mantle source (Fig. 12). Although some basalts with extreme geochemical signatures (nephelinites and potassic/ultrapotassic basalts) may have distinct origins (mantle transition zone, Sakuyama et al., 2013; Wang et al., 2017; Xu et al., 2020; Zeng et al., 2021), most of the alkaline basalts in Central-East Asia generally have overlapping geochemical features and similar source components and melting conditions (Figs. 6, 7, 11, 12). These characteristics are difficult to reconcile with those of previous models, including mantle plumes,
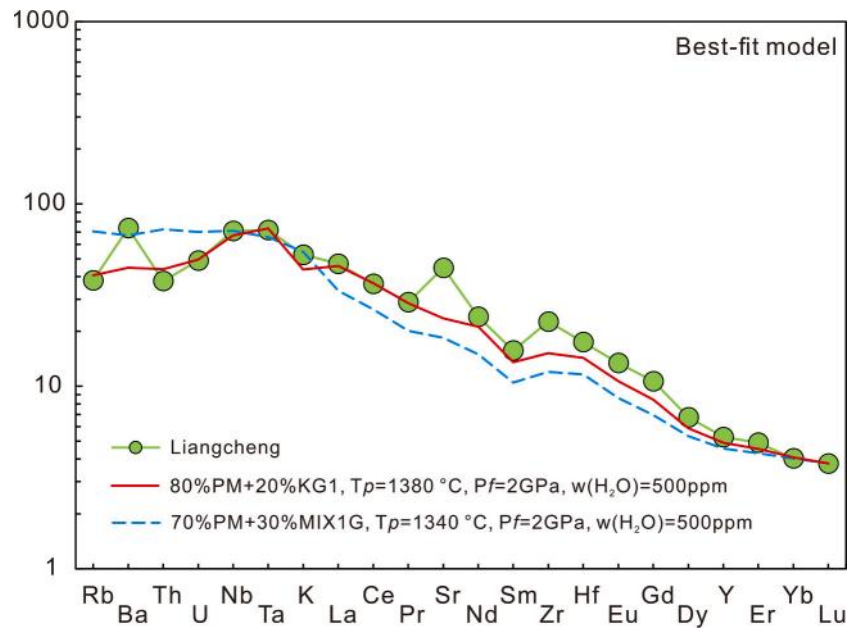

Fig. 10. Modeled melt compositions that best fit the averaged Liangcheng basalts (MgO ≥ 8 wt%) (Brown and Lesher, 2016). KG1 and MIX1G represent the end-member of silica-deficient pyroxenite and PM represents the primitive mantle. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

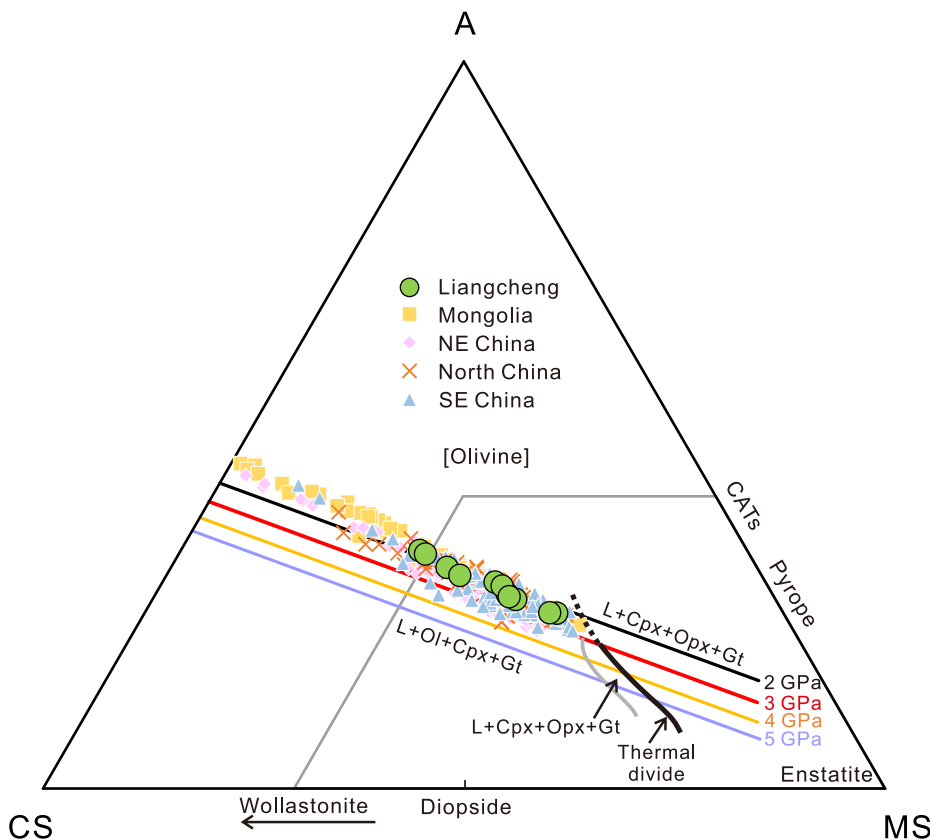

Fig. 11. A mole% pseudo ternary projection from or toward olivine into the CS-MS-A plane (Herzberg, 2011). The projection code follows O'Hara (1968), and the calculation method of cotectics is from Herzberg (2011). Abbreviations: L-liquid, Ol-olivine, Q-quartz, Cpx-clinopyroxene, Opx-orthopyroxene, Gt-garnet. All plotted basalts have high MgO contents (≥ 8 wt%) and plot on the CO_2-free side in the CaO vs. SiO_2 diagram (Fig. S7). Data for basalts from Mongolia, NE China, North China, and NE China are shown in Table S5, and data sources are identical to those in Fig. 7.

lithospheric rifting or delamination, or plate subduction. Instead, these similarities are likely the result of decompression melting of small-scale mantle convection due to regional lithospheric thickness variations. This proposal is consistent with recent studies suggesting that small-scale mantle convection driven by regional lithospheric thickness variations may have occurred beneath SE and NE China (Xu et al., 2022; Zhou et al., 2023). Similar small-scale convection has also been detected in the Baikal rift zone of Central Asia by geophysical observations and proposed to account for the intraplate magmatism in regions with thin lithosphere and sharp thickness variations, such as Southeast Australia, North America, and West Africa (Missenard and Cadoux, 2012; Davies and Rawlinson, 2014; Ballmer et al., 2015). Based on the above
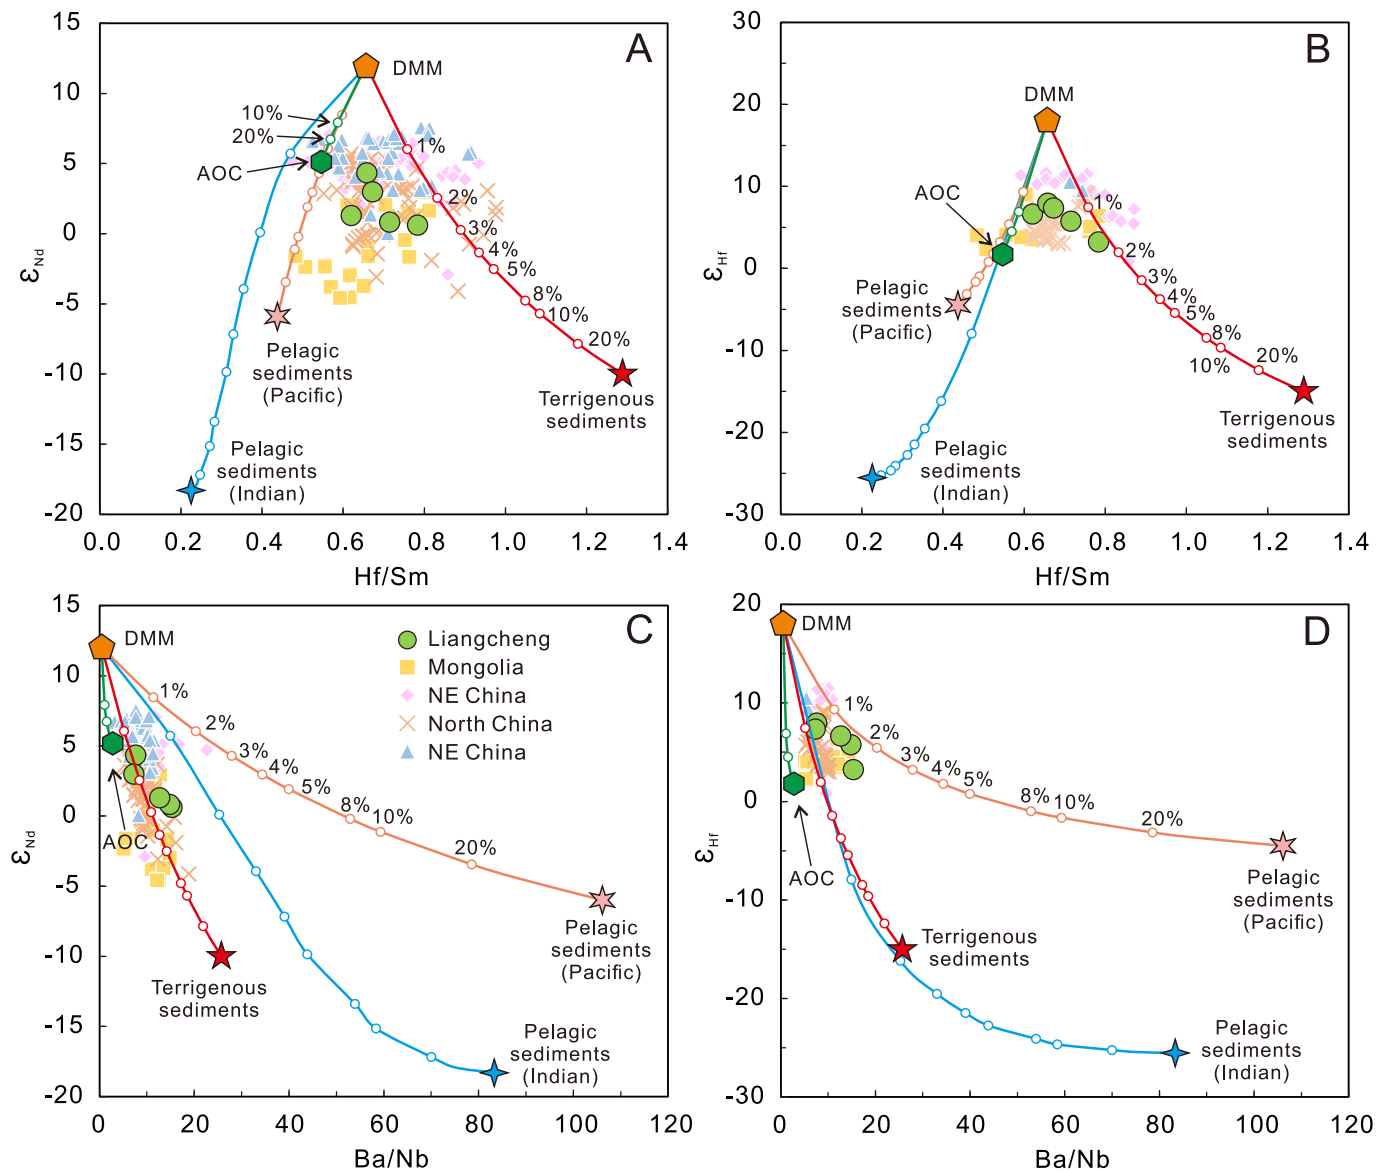

Fig. 12. (A) ε_{Nd} vs. Hf/Sm, (B) ε_{Hf} vs. Hf/Sm, (C) ε_{Nd} vs. Ba/Nb, (D) ε_{Hf} vs. Ba/Nb diagrams for the Liangcheng basalts. DMM is from Workman and Hart (2005); Altered oceanic crust (AOC) is from Rehka and Hofmann (1997) and Guo et al. (2009); Pelagic sediments from the western Pacific and Indian Ocean are according to Cousens et al. (1994) and Rehka and Hofmann (1997), respectively. Terrigenous sediment is from Wedepohl (1995) and Chauvel et al. (2014). Data for Cenozoic alkaline basalts from Mongolia, NE China, North China, and NE China are listed in Table S5, and data sources are the same as those in Fig. 7.

considerations, we suggest that edge-driven convection may be ubiquitous beneath Central-East Asia and probably plays an important role in the formation of pervasive Cenozoic small-volume alkaline basalts.

6. Conclusions

We conducted comprehensive geochemical studies and thermodynamic modeling of the Liangcheng basalts to explore the source characteristics and melting mechanisms of continental intraplate alkaline basalts beyond the Big Mantle Wedge. These basalts have a silica-deficient pyroxenite-bearing mantle source (20% silica-deficient pyroxenite +80% peridotite) with melting pressures and temperatures of ~2GPa and 1380 °C, respectively. Considering the relatively low melting pressure, regional lithospheric thickness variations, and tectonic history, we propose that edge-driven convection could be a likely mechanism for the studied basalts. Similar source characteristics, melting conditions, and geological distribution patterns between the Liangcheng basalt and many other regional Cenozoic alkaline basalts,

combined with similar lithospheric thickness variations observed beneath these basalts, suggest that edge-driven convection may be ubiquitous beneath Central-East Asia and that such a melting mechanism could serve as a major driving force for widespread continental intraplate basaltic magmatism.
